A method and apparatus for error-control

ng in a digital data communications system.

In order to ensure that a predetermined of a bit sequence to be transmitted is co received by a receiver, the predetermined extracted from the bit sequence. The ext bit is encoded and then combined with sequence which has not been extracted combined bit sequence is convolutionall coded and then transmitted to the receiver bit sequence transmitted under maximum-likelihood decoding using algorithm, wherein the information of the determined bit encoding is used to decoc predetermined bit. Subsequently, the en predetermined bit portion is extracted and jected to block decoding.

The present invention relates generally to a method and apparatus for implementing error-control coding in a digital data communications system, and more specifically to such a method and apparatus for correcting and/or detecting errors induced during data transmission.

Description of the Prior Art

In order to correct and/or detect channel bit errors induced during digital data transmission, it is well known in the art to utilize error-control coding techniques.

These techniques are disclosed in a book entitled "Essential of Error-coding Techniques" edited by Hideki IMAI and published 1990 by Academic Press Inc., San Diego, California 92101, U.S.A., and a book entitled "Error Control Coding: Fundamentals and Applications" by Shu Lin, et al., published 1983 by Prentice-Hall, Inc., Englewood Cliffs, N.J. 07632 U.S.A., merely by way of example.

Redundant bits are added to each binary code word to be transmitted in order to provide the code with the capability of combating the channel noises. Viterbi algorithm is able to exhibit error correcting capability almost equally over entire bits of a code word. However, it is sometimes required to transmit a special bit(s) of each code word with high reliability as compared with the remaining bits of the code word. In order to realize such a requirement, according to prior art, it has been inevitably required to provide a plurality of pairs of an encoder and decoder having different error-control capability or functions. However, the above mentioned known technique suffers from the drawback that an overall system is rendered large and complex. Further, the freedom of the system design is rendered.

SUMMARY OF THE INVENTION

An object of the present invention is to provide a method for error-control coding such that an important bit(s) is selected from a bit sequence and the subjected to block encoding for correctly transmitting same.

Another object of the present invention is to provide an apparatus for error-control coding such that an important bit(s) is selected from a bit sequence and then subjected to block encoding for correctly transmitting same.

In brief, the above objects are achieved by a technique wherein, in order to ensure that a predetermined bit(s) of a bit sequence to be transmitted is correctly received by a receiver, the predetermined bit is extracted from the bit sequence. The extracted bit is encoded and then combined with a bit sequence which has not been extracted. The combined bit sequence is convolutionally encoded and then transmi-

ted to the receiver. The bit sequence transmitted undergoes maximum-likelihood decoding using Viterbi algorithm, wherein the information of the predetermined bit encoding is used to decode the predetermined bit. Subsequently, the encoded predetermined bit portion is extracted and subjected to block decoding.

BRIEF DESCRIPTION OF THE DRAWINGS

The features and advantages of the present invention will become more clearly appreciated from the following description taken in conjunction with the accompanying drawings in which like elements are denoted by like reference numerals and in which:

Fig. 1 is a block diagram schematically showing a first embodiment of the present invention;
Fig. 2A is a sketch schematically showing waveforms of an analog signal to be encoded;
Fig. 2B is a diagram schematically showing burst digital signals to be transmitted;
Fig. 3 is a block diagram schematically showing an arrangement of a block of Fig. 1;
Fig. 4 is a known encoder state diagram by which the operations of the first embodiment are discussed;
Figs. 5-7 each is a trellis diagram by which the operations of the first embodiment are discussed;
Fig. 8 is a block diagram schematically showing a transmitter of a second embodiment;
Fig. 9 is a block diagram schematically showing a receiver of the second embodiment;
Fig. 10 is a block diagram schematically showing a transmitter of a third embodiment; and
Fig. 11 is a block diagram schematically showing a receiver of the third embodiment.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

A first embodiment of the present invention will be discussed with reference to Figs. 1-7.

Fig. 1 is a block diagram showing an arrangement of the first embodiment in block diagram form.

The arrangement of Fig. 1 generally includes a transmitter 10 which is interconnected to a receiver 12 via a transmission channel 14.

The transmitter 10 includes a message source 16, a source encoder 18, a bit selector 20, a block encoder 22, a bit combiner (or bit merger) 24, and a convolutional encoder 26, all of which are coupled as shown. On the other hand, the receiver 12 is comprised of a maximum likelihood decoder 28 which operates under Viterbi algorithm, a bit selector 30, a block decoder 32, a bit combiner 34, and a source decoder 36, all of which are coupled as illustrated.

Merely for the sake of a better understanding of the first embodiment, it is assumed that the message

source 16 takes the form of an analog speech signal source. The wave form of the speech signal (denote by "S1"), obtained from the source 16, is schematically shown in Fig. 2A. The speech signal S1 undergoes digital signal processing at the source encoder 18. That is, the speech signal is initially digitized at a time interval of 40 ms (for example) which is called as a frame. Subsequently, the digitized speech signal is compressed and then applied to the bit selector 20 as a bit sequence S2 in a burst mode as best seen from Fig. 2B. If the bit rate of digitization is 4K bits/sec, it is readily appreciated that each frame of 40 ms contains 160 bits. It is further assumed that the first bit of the burst signal is a mode bit indicating whether the corresponding frame is a voice frame or a silence frame. This mode bit appearing at the beginning of each frame is very important and hence has to be correctly transmitted to the receiver 12. The second to the last bits of each frame is not so important as compared with the mode bit.

The bit selector 20 selects the above mentioned mode bit from the incoming frame data. This bit selection is carried out under control of a bit select signal applied to the selector 20 from a central processing unit (CPU) (not shown) which supervises the overall operation of the transmitter 10. The other bits which have not been selected by the bit selector 20 are directly supplied to the bit combiner 24.

The mode bit thus selected is fed to the block encoder 22 which, in this particular embodiment, outputs "01" and "10" when the applied mode bit assumes "0" and "1", respectively. The bit combiner 24 combines or merges the two outputs of the block encoder 22 and the bit selector 20 in this order. A bit sequence (depicted by "A") from the bit combiner 24 is applied to the convolutional encoder 26.

In the foregoing, it is assumed that a given frame of the bit sequence S2 outputted from the source encoder 18 is represented by

$$S2 = (0\ 0\ 0\ 1\ \dots) \quad (1)$$

As mentioned above, if the mode bit is "0" then the output of the block encoder 22 assumes "01". Thus, the combiner 24 issues the output A which is given by

$$A = (0\ 1\ 0\ 0\ 1\ \dots) \quad (2)$$

Reference is made to Fig. 3 wherein the arrangement of the convolutional encoder 26 is shown in block diagram form. The encoder 26 is of a convolutional type and includes three delay lines or shift registers (denoted by D_n , D_{n-1} and D_{n-2}), two modulo-adders 40a-40b, and a parallel/serial (P/S) converter 42, in this particular embodiment. Thus, the constraint length (K) of the encoder 26 is 3 (three) while the code rate (R) thereof is 1/2. The arrangement is illustrated in Fig. 3 is well known in the art.

Fig. 4 is a state diagram of the encoder 26. In Fig. 4, two consecutive bits within each of ovals indicate the bits held in the last two delay lines D_{n-2} and D_{n-1} and indicates an encoder state. The encoder state

(00), (01), (10) and (11) are connected or looped by solid and broken arrow lines. If a bit "1" is applied to the encoder 26, the encoder state is shifted to the other state or returned to the same state along the solid arrow. On the other hand, if a bit "0" is applied to the encoder 26 then the encoder state is shifted to the other state or returned to the same state along the broken arrow. The outputs of the convolutional encoder 26 are represented along the corresponding arrows such as (00), (01), (10) and (11).

The encoder 26 is set to the state (00) before a burst type bit sequence is newly applied. Therefore, if the mode bit (viz., first bit) assuming "0" is applied to the encoder 26, the encoder state (00) remains unchanged. In this case, the output of the encoder 26 is (00). Following this, if the second bit assuming "1" is applied to the encoder 26, the encoder 26 takes the state (01) and outputs two bits sequence (11). Thereafter, similar operations continue. Thus, if the bit sequence A of (0 1 0 0 1 ...) is applied to the convolutional encoder 26 as mentioned in expression (2), the bit sequence C obtained from the encoder 26 and then sent over the channel 14 is given by

$$C = (00\ 11\ 01\ 11\ 11\ \dots) \quad (3)$$

The bit sequence C is transmitted over the channel 14 and applied to the receiver 12 as a bit sequence CC. It is assumed the bit sequence C is subjected to bit errors during transmission and that the bit sequence CC is represented by

$$CC = (01\ 11\ 01\ 01\ 11\ \dots) \quad (4)$$

The operations of the maximum-likelihood decoder 28 of the receiver 12 will be discussed with reference to trellis diagrams shown in Figs. 5-7. The above mentioned bit sequences A, C and CC, given by expressions (2)-(4) are shown at the top portions of each of Figs. 5-7. It is well known that the trellis diagram represents the encoder states (see Fig. 4) along a time axis. It should be noted in Figs. 5-7 that numerals above the encoder states represent respectively "decimal numbers" indicating path metrics.

Reference is made to Fig. 5. The decoder 28 is initialized such that the path metric of the encoder state (00) is set to 0 while each of the remaining path metrics of the other states (01), (10) and (11) is set to a sufficiently large number such as 10 (decimal) in this particular embodiment. These path metrics are illustrated at the first time point ($t=0$).

The decoder 28 initially decodes the first two bits (viz., encoded mode bit) using the previously known block code information (01 and 10). This information has been stored in a suitable memory in the receiver 12 and is applied to the decoder 28.

The first bit sequences have been block encoded at the encoder 22, it is thus appreciated that survivor paths at $t=1$ and $t=2$ are represented by two bold solid lines and two bold broken lines as illustrated.

A bit sequence of the survivor path extending to the state (00) at $t=2$ is (00), and hence, this path is un-

able to be finally selected. Further, a bit sequence of the survivor path extending to the state (11) at $t=2$ is (11). Therefore, this path is expected to finally be selected. On the other hand, the survivor path extending to the state (10) at $t=2$ can be expected to be chosen for determining the decoded sequence, while the survivor path extending to the state (11) at $t=2$ can not be expected to be used to determine the decoded sequence.

Therefore, in order to determine the following survivor paths, path metrics at the states (00) and (11) both $t=2$ are set to sufficiently large number such as 10 (decimal) in this case, as shown in Fig. 6. This is to exclude the survivor paths which can not eventually be used for estimating the incoming bit sequence.

Subsequently, conventional decoding according to Viterbi algorithm is implemented which is well known in the art and thus will not be discussed for the sake of brevity. Survivor paths determined up to $t=2$ are illustrated by bold solid and broken lines in Fig. 7.

The decoded bit sequence from the maximum likelihood decoder 28, is then applied to the bit selector 30. This selector 30 implements the reverse operation of the counterpart thereof 20 in response to a bit select signal which has previously stored in the receiver 12. The first two bits of the frame are applied to the block decoder 32 while the remaining bits are directly applied to the bit combiner 34. The bit selector 30 decodes the first two bits to "0" or "1" and then applies the decoded bit to the bit combiner 34. The bit sequence aligned at the bit combiner 34 is applied to the source decoder 36 which produces an estimate message.

In the aforesaid first embodiment, the mode information is a single bit. However, it is within the scope of the present invention to set the mode information to two or more than two bits in order to meet applications. Further, the bit combiner 24 is arranged to insert the output of the block encoder 22 into a given position of the bit stream applied thereto from the bit selector 20.

Reference is made to Figs. 8 and 9, wherein a second embodiment of the present invention is schematically shown in block diagram. The second embodiment is an error-control coding apparatus which includes both error-correcting and error-detecting functions. Figs. 8 and 9 show respectively a transmitter and receiver of the second embodiment.

The transmitter shown in Fig. 8 further includes a switch 60 and two error-detecting encoders 62a and 62b as compared with the counterpart of the first embodiment. Accordingly, the blocks of Fig. 8 which have been referred to in the first embodiment, will be described only if they are directly relevant to the second embodiment.

The mode bit obtained from the bit selector 20 is applied to the switch 60 as a switch control signal. The

remaining bits from the bit selector 20 are applied to the switch 60. If the mode bit assumes a logic "0", the switch 60 allows the incoming bit sequence to be applied to the error-detecting encoder 62a. Contrarily, if the mode bit assumes a logic "1" then the switch 60 applies the incoming bit sequence to the other encoder 62b.

As is known, an error-detecting encoder is to add redundant bits to a bit sequence (viz., detection bits) applied thereto for the purpose of error detection.

In the second embodiment, the encoders 62a and 62b add the same length of redundant bits to the bit sequences applied thereto. However, the two encoders 62a and 62b produce or arrange different redundant bits with each other. This is very preferable in the case where significant bits are different depending on a logic level of the mode bit (viz., whether the frame data is a voice mode or not in this particular embodiment).

The receiver shown in Fig. 9 includes a switch 64 and two error-detecting decoders 64a and 64b in addition to the receiver 12 of the first embodiment. Accordingly, the blocks of Fig. 9 which have been referred to in the first embodiment, will be described only if they are directly relevant to the second embodiment.

The decoded mode bit obtained from the block decoder 32 is applied to the switch 64 as a switch control signal. The bit sequence except for the mode bit, outputted from the bit selector 30, is applied to the switch 64. If the decoded mode bit (viz., switch control signal) assumes a logic "0", the switch 64 allows the incoming bit sequence to be applied to the error-detecting decoder 64a. Contrarily, if the decoded mode bit assumes a logic "1", the switch 64 applies the incoming bit sequence to the other decoder 64b.

Each of the error detecting decoders 64a and 64b outputs an error detect bit indicating whether or not the received bit sequence includes an error. Further, the decoders 64a and 64b apply respectively the decoded bit sequences to the bit combiner 34. The following operations are essentially the same as those mentioned in connection with the first embodiment.

Another feature of the second embodiment is that if the mode bit is erroneously transmitted, each of the decoders 64a and 64b issues the error detect bit which indicates the presence of transmission error. This is very advantageous in that the mode bit is the nature of being correctly transmitted as mentioned above.

Reference is made to Figs. 10 and 11, wherein a third embodiment of the present invention is schematically shown in block diagram. The third embodiment is an error-control coding apparatus which includes both error-correcting and error-detecting functions. Figs. 10 and 11 show respectively a transmitter and receiver of the third embodiment.

The transmitter shown in Fig. 10 further includes

a bit selector 70 and an error-detecting encoder 72 as compared with the counterpart 10 of the first embodiment. Accordingly, the blocks of Fig. 10 which have been referred to in the first embodiment, will be described only if they are directly relevant to the third embodiment.

The mode bit obtained from the bit selector 20 is applied to the bit selector 70 as a bit select signal. The remaining bits of a frame, outputted from the bit selector 20, are applied to the bit selector 70. The mode bit applied to the bit selector 70 determines which portion of the bit sequence applied thereto should be transferred to the error-detecting encoder 72. The number of consecutive bits selected depending on logic level of the mode bit, is usually different from that selected in response to the other logic level of the mode bit. This is very advantageous in the case where significant bits are different in position depending on the logic levels of the mode bit (viz whether the frame data is a voice mode or not in the particular embodiment). The bit combiner 24 combines the outputs of the blocks 22, 70 and 72.

Fig. 11 shows a receiver of the third embodiment. The operations of this embodiment is readily appreciated from the foregoing and thus, the description thereof will be omitted for brevity.

It will be understood that the above disclosure is representative of only three possible embodiments and that various modifications can be made without departing from the concept of the invention.

Claims

1. An apparatus for error-control coding, comprising:
 - first means for selecting at least one bit from a bit sequence applied thereto;
 - second means for encoding said at least one bit applied thereto from said first means;
 - third means for combining the output of said second means and a bit sequence which has not been selected at said first means;
 - fourth means for implementing convolutional encoding to the bit sequence outputted from said third means;
 - fifth means for implementing maximum likelihood decoding to the bit sequence transmitted; and
 - sixth means for block decoding the block-encoded bit data.
